ClinicOS

An AI Clinic Operating System for Clinics and Hospitals, in India and Beyond

Problem Statement

---

1. Background and Context

India's primary healthcare system runs on a very large number of small, independently run clinics and single-doctor outpatient (OPD) practices, in cities and towns alike. Across solo chambers, multi-doctor clinics and hospital outpatient departments, a typical general physician sees dozens of patients a day, largely paid for in cash, with no dedicated administrative or IT staff. Consultation notes, prescriptions, and patient history are still recorded by hand or typed slowly between patients, if they are recorded in a structured, reusable form at all. At the same time, India's digital health infrastructure is expanding quickly: the Ayushmaan Bharat Digital Mission (ABDM) has already issued over 70 crore health IDs (ABHA) and registered lakhs of clinics in its Health Facility Registry, and large well-funded platforms such as Eka Care and HealthPlix are building AI scribes and digital EMRs for the Indian market. Most of these platforms are built primarily for hospitals and clinic chains, without giving equal attention to the solo doctor who has never used clinic software before and has no one to call for support. ClinicOS is designed to close that gap from both directions at once. It is aimed just as much at solo practitioners as it is at larger clinics and hospital networks, and the ambition behind it is not limited to India: the same documentation problem exists for doctors everywhere, which makes ClinicOS a product with a national and, eventually, an international market.

2. Empathize: Understanding the Stakeholders

Field conversations with practising doctors and observation of a real busy OPD practice surfaced the following recurring pain points, grouped by who experiences them:

Doctors / Clinic Owners

- Writing or typing consultation notes competes directly with time that could be spent seeing the next patient, especially in high-volume, cash-pay OPD settings.
- Handwritten notes and paper prescriptions are illegible, get lost, and cannot be searched or reused for a returning patient's history.
- Existing EMR products are built assuming hospital-scale IT support, ABDM compliance staff, and English-first, keyboard-heavy workflows — not a solo doctor speaking Bengali or Hindi with no technical background.

Patients

- Prescriptions are often handwritten and hard to read at the pharmacy, increasing the risk of a wrong medicine or dose being dispensed.
- There is no simple, persistent record of past visits, diagnoses, or medication history that a patient can carry between visits or share with another doctor.
- Chronic-disease patients (hypertension, diabetes) have no structured way to report home readings between visits, so deterioration is often caught only at the next in-person visit.

The Wider System

- India's push toward ABDM-linked digital health records assumes clinics are digitally onboarded; small, independent clinics are the segment furthest behind on this, risking exclusion from national health schemes and referral networks as compliance tightens.
- Existing commercial chronic-disease monitoring tools for small clinics are essentially absent; the closest equivalent (the government's SIMPLE hypertension programme) is a public health initiative operated by frontline workers, not a product a clinic can adopt itself.

3. Define: Problem Statement

Doctors in India, from solo practitioners to larger clinics and hospitals, lack an affordable, easy-to-adopt digital tool that turns a normal spoken consultation — conducted in Bengali, Hindi, English, or a mix of the three — directly into a structured, legible medical record and prescription, without demanding IT staff, English-only input, or a workflow that only works at one end of that scale.

> *"How might we let any Indian doctor, whether working alone or as part of a larger institution, produce a clear, structured, reusable medical record from an ordinary spoken consultation, in their own language, without adding a single minute of extra administrative work to their day?"*

4. Root Cause Analysis

The underlying causes of this problem are structural, not a matter of individual doctors being unwilling to adopt technology:

- **Language mismatch.** Consultations happen in regional languages and code-switched speech; most clinic software and even many AI scribes are tuned primarily for English or a narrow set of languages, so transcription and structuring quality drops exactly where it is needed most.
- **Wrong customer, wrong design.** Enterprise-grade EMR and scribe platforms are designed, priced, and supported for hospitals and clinic chains with dedicated administrative staff, which is a completely different buyer and workflow from a single doctor running their own practice.
- **No time to learn new software.** A solo doctor cannot spend hours in training or configuration between patients; any tool that adds friction to the existing spoken-consultation habit will simply not be used past the first day.
- **Trust and data sensitivity.** Clinical conversations are highly sensitive; doctors and patients are reasonably cautious about a platform that permanently stores raw audio of consultations on a third-party server.

5. Ideate: Proposed Solution

ClinicOS is proposed as an AI-based clinic operating system built to work equally well for a solo practitioner and for a larger clinic or hospital, starting with an AI medical scribe and expanding into a connected set of tools along a single patient journey. Because the underlying scribe, note-structuring, and record-keeping technology is not tied to any one practice size, the same core product is designed

to scale from a single-doctor OPD to hospitals and national health systems, and eventually to markets outside India.

- **AI Scribe.** The doctor consults normally, speaking in Bengali, Hindi, English, or a mix; the system listens, transcribes, and automatically structures the conversation into a clinical note (chief complaint, history, examination findings, diagnosis) for the doctor to review and sign — not to replace their judgement, but to remove the manual writing step.
- **Structured Note and Printable Prescription.** Once signed, the note generates a clean, legible, printable prescription in a standard format, reducing pharmacy misreads and giving the patient a professional, reusable document.
- **Patient Timeline.** Every signed visit is stored as structured text (not audio), so a returning patient's history, past diagnoses, and prescriptions are searchable and available at the next visit, even at a clinic with no formal record-keeping system today.
- **Chronic Monitoring (planned).** Patients with hypertension or diabetes can log home readings between visits, feeding a timeline the doctor can review, so deterioration is not caught only at the next scheduled appointment.
- **Referral Routing (planned).** A structured record makes it possible to route a patient to a specialist or higher facility with their history intact, rather than starting from zero at every referral. A deliberate product decision underpins the whole system: the raw audio of a consultation is deleted the moment the doctor signs the structured note. Only the reviewed text is kept. This directly addresses the trust concern identified in the empathize stage, without needing the doctor or patient to configure any privacy setting themselves.

6. Scope and Phased Roadmap

The problem is addressed incrementally, so that each phase is validated with real doctors before the next is built:

Phase	Capability	Status
1	AI scribe: speech → structured clinical note	Working prototype
2	Printable prescription + searchable patient timeline	Working prototype
3	Chronic-disease home-reading monitoring	Planned
4	Referral routing with intact patient history	Planned

The plan from the start is staged: single-doctor and small clinics first, where fast, hands-on iteration with real doctors is possible for a small team; then multi-doctor clinics, hospitals and health systems; then international markets. Initial validation runs with doctors across practice sizes.

7. Constraints and Assumptions

- **Regulatory boundary.** Under CDSCO's software guidance, tools limited to data transfer, storage, formatting, and communication (Phases 1–2) fall outside medical device regulation. Chronic-disease monitoring that quantifies physiological readings and raises risk alerts (Phase 3) is likely

to fall under regulated Software as a Medical Device (SaMD), so this phase must be designed and scoped deliberately rather than assumed to be exempt.

- **Data sensitivity.** Only structured, doctor-reviewed text is retained; raw audio is not kept beyond the point of sign-off, which constrains what can later be used for model retraining (e.g. audio-level speech model fine-tuning is not possible without a separate, explicitly consented data-collection process).
- **Resource constraints.** The initial build and pilot are run by a small student team with limited compute and no dedicated support staff, so the solution must be evaluated for real-world adoption at 3–5 clinics before any claim of wider scalability is made.
- **Existing competition.** Larger, well-funded platforms (Eka Care, HealthPlix) already offer AI scribes and multilingual support. ClinicOS's advantage over them is the combination of features taken together, not any single one in isolation: deletion-on-sign-off privacy, a design that works for solo practices and larger institutions alike, and a connected product loop from scribe through to chronic monitoring and referrals that no single competitor currently offers as one system.

8. Expected Outcome and Impact

If successful, ClinicOS should measurably reduce the time a doctor spends on documentation per consultation and produce a legible, reusable medical record for every patient visit, whether that doctor is running a single room alone or working inside a much larger institution. Because the same core product serves both ends of that range, the path to a national and eventually international product runs through the same technology validated here, not a separate one built later. Success will be evaluated against concrete, pre-defined field validation criteria (doctor-reported time saved, unattended day-21 usage, and real clinic willingness to pay) rather than survey-based interest alone.

Prepared as a Design Thinking problem statement for ClinicOS, an in-development AI clinic operating system for practices of every size — clinics first, then hospitals and health systems — with a national and international market in view.
